ABSTRACT
The objective of this review is to illustrate the broad spectrum of papillary lesions that can be found in breast fine needle aspirations (FNAC).

Papillary tumors of the breast comprise lesions of variable morphology and include entities ranging from benign to high grade malignant. Features of papillary neoplasms invariably describe branching three-dimensional papillary clusters with delicate fibrovascular cords. Cytomorphological criteria for benign and low-grade malignant entities overlap and a definite cytological diagnosis is not always possible. Cellular papillomas may harbor areas of ductal carcinoma in situ (DCIS), atypical ductal hyperplasia (ADH) or lobular neoplasia. DCIS can be both high grade and non-high grade. Immunocytochemistry (ICC) can be helpful, providing there is adequate material for ICC. Relatively high error rates, false negatives as well as false positive diagnoses can be found. In general, papillary lesions may be recognized as such. Reporting strategies will often recommend caution if trying to differentiate benign, cellular papillomas from low-grade carcinomas.

In conclusion, papillary lesions present with a broad spectrum of cytomorphological features that are illustrated in this review.

INTRODUCTION
Papillary tumors of the breast comprise lesions of variable morphology and include entities ranging from benign to high grade malignant (table 1). A papillary neoplasm is histologically one that exhibits an arborescent epithelial proliferation with fibrovascular cores and is attached by a stalk to the wall of a dilated duct. They constitute < 2 % of all breast lesions.

Cytomorphological criteria for benign and low-grade malignant entities overlap and a definite cytological diagnosis is not always possible. Features of papillary neoplasms invariably describe branching three-dimensional papillary clusters with delicate fibrovascular cords [1-6]. Additional features of papillary carcinomas include moderate to abundant cellular material [2-4], small papillae arranged in cell balls, tall columnar cells, isolated naked nuclei and hemosiderin laden macrophages [2, 3], irregular groups of predominantly monolayered (two-dimensional) epithelium composed of small, polygonal or cuboidal cells with eosinophilic cytoplasm and rounded, eccentrically placed nuclei [2, 3, 7-19]. Features indicating a benign papillary lesion include less cell material, papillae with cohesive stalks surrounded by columnar cells in a honeycomb pattern, apocrine metaplasia, bipolar naked nuclei as well as fewer small papillae and isolated columnar cells [2, 3]. Myoepithelial cells within clusters and inconspicuous naked, bipolar nuclei in the background also indicate a benign lesion [2, 5].
Tse et al report considerable overlaps in the criteria [19] and no demonstrable quantitative differences between papilloma and papillary carcinoma (PC), but with a qualitatively higher degree of atypia in PC and more elaborate and slender papillary fragments. Haji et al found loose cohesive clusters and acinar formation of neoplastic cells to be significant parameters differentiating PC from benign papillomas [20].

Reported accuracy rates in the literature are given as 27 % - 88 % for all papillary lesions [10, 19, 21, 22] and 91 % for PC alone [18]. Prathiba et al and Jayaram et al reported a sensitivity of 42% and 73%, respectively [10, 15] and a specificity of 88.3 % [23]. Relatively high error rates, false negatives (FN) as well as false positive (FP) diagnoses are reported [11, 15, 18, 19].

Not all lesions diagnosed as papillary on cytology are papillary on histology, the most common error being fibroadenomas and fibrocystic changes [10, 18, 21, 24] but in general, papillary lesions can be diagnosed as such [2, 6, 7, 10, 12, 21].

The known and reported criteria of papillary lesions are almost exclusively based on conventional smears. Many institutions now use liquid based preparations (LBC) alone or as an adjunct to traditional smears. Several features may change and appear different in LBC and could potentially cause both FN and FP diagnoses [24].

The aim of this review is to illustrate the broad spectrum of papillary lesions that can be found in breast FNAC.

**Table 2: Cytological findings in (benign) intraductal papillomas.**

- Variable cellularity with a basic benign pattern
  - Epithelial components:
    - Cohesive papillary clusters
    - (Micro-) papillary clusters, bipolar cells
    - Complex, folded, monolayer or three dimensional epithelial aggregates
    - Small groups and monolayer sheets
    - Benign nuclei or nuclei showing moderate to distinct cellular/nuclear pleomorphism but with a fine chromatin pattern
    - Nucleoli may be distinct
    - Hyperplasia with and without atypia showing a mixed cell population, both benign and irregular/atypical with three dimensional aggregates that may resemble ADH/low grade DCIS (solid and/or cribriform)
    - Usually the epithelial fragments are rather cohesive
    - A (usually small) population of single cells is not uncommon
  - Myoepithelial cells/nuclei
  - Apocrine cells
- Stromal fragments, partly papillary with vascular core
- Debris and macrophages
The “plain” papillomas have a moderate cellularity, sheets and groups of benign ductal cells, as well as macrophages and often also apocrine cells. These lesions are cytologically completely benign. Traditionally they are surgically excised, but some argue that it is not mandatory [22, 26]. Papeix et al. found that 34/36 cases diagnosed as benign with papillary features were indeed benign papillomas and the two remaining cases were stable on radiological follow up.

Proliferative lesions tend to be cellular and with a polymorph population consisting of several cell types (benign/usual intra-ductal hyperplasia = UDH), all with basically benign nuclear criteria (Figure 2 a–f).
Figure 2: Cellular, benign papilloma

a. Magnification x 100, MGG. Cellular material with stromal fragment, irregular sheets, groups and aggregates of ductal cells as well as a single cell population.

b. Magnification x 200, MGG. Smaller groups and sheets, mixed ductal and apocrine as well as numerous macrophages. In addition a minor single cell population.

c. Magnification x 200, MGG. Cellular papilloma with threedimensional epithelial clusters and metachromatic basement membrane-like globules

d. Magnification x 200, MGG. Complex epithelial sheets with transition from ductal to apocrine cell type.

e. Magnification x 400, MGG. Cellular polymorphism in a papilloma with extensive, but histologically benign hyperplasia. Nuclear irregularities, but uniform chromatin structure.

f. Magnification x 200, HE. Proliferative papilloma with adenosis; same lesion as 2e.

They may harbor areas of ductal carcinoma in situ (DCIS), atypical ductal hyperplasia (ADH) or lobular neoplasia. DCIS can be both high grade and non-high grade. Cells from high grade DCIS are clearly recognized as malignant [27], whereas aggregates and single cells from a non-high grade lesions may not be definitely identified in the smears. In many cases though, the atypical cells may not present in the specimens. Immunocytochemistry can be helpful, providing there is adequate material for ICC (Table 3). These cellular and heterogeneous papillary lesions should be diagnosed as equivocal/atypical and surgically excised.

Table 3: Overview of papillary lesions and their immunophenotypes.

Florid papillomatosis of the nipple (subareolar papillomatosis) is a benign epithelial proliferation localized within and around the collecting ducts of the nipple. It comprises < 1% of breast specimens and has an age range of 20-87 yrs (mean 43 yrs). Approximately 2/3 of the women presents with nipple discharge. Some cases may have skin erosion and mimic Paget’s disease of the nipple clinically [25]. The cytologic findings are listed in (Table 4) and they are illustrated in (Figure 3 a-g). If palpable, the clinical findings are usually very characteristic and help making a confident diagnosis. The FNAC material is moderate to abundant and can be prepared both as smears, as LBC and as cell block (Figure 4 a-e). ICC phenotype (Table 2) reveal a benign, polymorph cell composition and supports the diagnosis of a benign lesion.

Figure 3: Subareolar papillomatosis.
a. Magnification x 50; HE, cell block. FNAC material from a cellular papillary lesion located in the nipple.
b. Magnification x 50, MGG. Abundant cellularity with large, complex and folding epithelial aggregates
c. Magnification x 100, MGG. Complex cohesive aggregates
d. Magnification x 100, MGG. Complex aggregate with part of the stromal papillary stalk and a minor component of single cells
e. Magnification x 100, MGG. Irregular, medium sized aggregates, both ductal and apocrine.
f. Magnification x 200, MGG. Micropapillary structures
g. Magnification x 400, MGG. Very regular, benign nuclei with uniform chromatin structure

Table 4: Cytologic findings in subareolar papillomatosis.
- Moderate or high cellularity with a basic benign pattern
- Small amount of debris, inflammatory cells and siderophages may be found
- Aggregates and smaller epithelial groups
- Basically cohesive, irregular aggregates
- Irregular shapes
- Micropapillary, macrophages, naked nuclei
- Uniform nuclei with finely distributed chromatin and small nucleoli
- Little anisonucleosis, occasional hyperchromatic nuclei possible
- Occasional dispersed epithelial cells
- Apocrine cells may be present

Papillary carcinoma variants

Intraductal papillary carcinoma in situ may present with a clear or blood stained nipple discharge. More peripheral lesions may present as a mass. Radiologically it can present both as a single, round and partly cystic lesion as well as micro-calcifications (as part of a DCIS) without a tumor [25]. In histology, we find ducts or TDLU (terminal duct-lobular unit) with slender branching fibro-vascular stalks covered by a single cell population of neoplastic cells (Figure 5 a-k). Micro-papillary, cribriform and solid growth patterns are also seen. The papillae are lined by neoplastic, columnar cells in one or several layers. The cells are deceptively bland with low-grade atypia. The cytological findings mirror the histology and are detailed in Table 5.
Figure 5: intraductal papillary carcinoma (papillary DCIS).

a. Magnification x 100, HE. Slender papillary structures lined by one layer of epithelial cells with low-grade nuclear atypia and delicate fibrovascular stalks.

b. Magnification x 50, MGG. Overview of smear with large papillary aggregate and numerous cell groups of varying sizes.

c. Magnification x 100, MGG. On larger magnification the branching capillaries are seen.

d. Magnification x 200, MGG. A smaller papillary fragment with central capillary surrounded by low-grade atypical cells. There is mild to moderate nuclear pleomorphism and scattered single cells.

e. Magnification x 400, MGG. On larger magnification a fine to somewhat coarse chromatin is seen and inconspicuous nucleoli.

f. Magnification x 400, MGG. Micropapillary epithelial cell group with low-grade nuclear atypia.

g. Magnification x 400, MGG. Smaller epithelial cell groups with low-grade nuclear atypia.

h. Magnification x 200, HE. Micropapillary epithelial proliferations with varying nuclear atypia, up to high grade (G1-3).

i. Magnification x 200, HE. Papillary epithelial proliferation with high grade atypical nuclei (G3).

j. Magnification x 400, MGG. Micropapillary DCIS G1-3 with proteineous debris, macrophages and micropapillary epithelial cell groups. One of the micropapillary groups shows a low-grade nuclear atypia whereas the rest are high grade with prominent pleomorphism.

k. Magnification x 400, PAP. Loosely cohesive sheet with high grade malignant cells: coarse irregularities in the nuclear contour, irregular peripheral chromatin brim, coarse nuclear chromatin with clearing and prominent nucleoli. Cytoplasmatic vacuolization is seen in some of the cells.

Encapsulated papillary carcinoma

[25] is a variant of papillary carcinoma characterized by fine fibrovascular cores covered by neoplastic cells of low or intermediate grade and surrounded by a thick fibrous capsule (figure 6a). In the majority of cases there are no myoepithelial cell layer within the papillae or at the periphery of the lesion.
There is a circumscribed round mass on mammography and ultrasound imaging. A frank invasive component is usually IDC and cannot be appreciated in the cytological material. Nipple discharge may be present. Cytologically the features (Figure 6b-g) are the same as the intraductal papillary carcinoma (Table 5), and the two entities can only be distinguished histologically.
Solid papillary carcinoma [25] represents < 1 % of breast carcinomas. It occurs usually in menopausal women with a mean in the seventh decade. About 20-25 % have a bloody discharge. Mammography may show an abnormality or lobular lesion. Ultrasound may also show a lobulated mass that histologically (Figure 7a,b) corresponds to closely apposed, expanse nodules with delicate fibrovascular cores within the nodules. These tumors often reveal neuroendocrine differentiation and/or mucinous components. Conventional invasive growth may be present, often having mucinous or neuroendocrine features [28, 29]. The cytological features resemble the two above subtypes of papillary carcinomas (Table 5) (Figure 7c-h). The cystic component is virtually absent, and debris and macrophages are not present. The features and findings of the epithelial cells, though, are virtually the same as the two above. Images illustrating the findings are seen in figures 7c-h. The cytological criteria are those of a low - grade carcinoma [28]. The presence of an eventual additionally invasive component cannot be evaluated in these three lesions. Primary surgery should then be complete excision, but should not include removal of the sentinel node (SN) or extensive surgery.

An overview and comparison of cytological features and immunocytochemical findings in benign and malignant papillary lesions is given in tables 3 and 6.

---

**Table 5: Cytological features of papillary carcinomas (intraductal, encapsulated and solid).**

- May be cystic on aspiration
- Cell material is usually abundant
- Epithelial cells are monotonous and appear “monoclonal” showing low grade nuclear/cell atypia (usually G1)
- Anisonucleosis, hyperchromasia, coarse chromatin and prominent nucleoli are uncommon (occasionally G2-G3).
- Benign bipolar cells are absent from the background, myoepithelial cells are not seen within the groups or are very scarce
- Large papillary cell clusters forming arborizing arrays bearing overlapping, palisaded cells on a fibrovascular core may be present (as in papilloma)
- Cells may be dispersed and the fibrovascular cores denuded
- (pseudo-)papillary arrangement of cells (in the solid-papillary type)
- Micropapillary as well as irregular small epithelial cell groups
- The epithelial cells are often distinctly columnar in appearance
- Evaluation of invasive component not possible
- Microcalcifications are common findings
- Intracytoplasmic vacuoles are not rare
- Neuroendocrine differentiation common in solid-papillary type
- Often extensive dissociation in single cells, plasmacytoid
Figure 7: Solid-papillary carcinoma.
a. Magnification x 50, HE. Solid growing carcinoma with a well demarcated border
b. Magnification x 200, HE. Low-grade nuclear atypia and intratumoral branching vessels.
c. Magnification x 100, MGG. Abundant cell material with large, pseudopapillary and three-dimensional epithelial aggregates, smaller groups and a large single cell population
d. Magnification x 100, MGG. Loosely cohesive cells with abundant single cells
e. Magnification x 100, PAP. Large, three-dimensional aggregates, loosely cohesive cells
f. Magnification x 400, MGG. Loosely cohesive, low-grade carcinoma cells with plasmacytoid appearance. Microcalcification (arrow).
g. Magnification x 400, PAP, SurePath. Mainly single cell population of plasmacytoid cells with delicate, finely granular chromatin and small, but visible nucleoli
h. Magnification x 400, PAP. Abundant, loosely cohesive and plasmacytoid cells. The chromatin if fine granular, but more distinct than in the SurePath preparation. Nucleoli are small, but distinct.

Invasive micropapillary carcinomas [25] are composed of small, hollow and morula-like clusters of cancer cells and surrounded by clear stromal places (Figure 8a). There is usually a reversed polarity, an “in side out” growth pattern, whereby the apical pole of the cells faces the stroma and not the luminal surface. They make up 0.9-2 % of invasive breast cancers [4], but up to 7.4 % off invasive breast cancers may have partial micropapillary growth pattern [5]. The mean age is as in IDC, 75 % are grade 2 and 3, estrogen and progesterone receptors (ER/PgR) are usually positive, whereas HER-2 is variable, but often positive. They usually present as a palpable mass. Cytologically these present as high grade carcinoma cells in well demarcated, angulated micropapillary groups lacking a fibrovascular core with irregular crowded nuclei (Figure 8b-d) and are clearly malignant [30-32].

According to the WHO (world health organization) definition [25], invasive papillary carcinoma is a tumor with predominantly papillary growth pattern (> 90 %) in the invasive component. It is a rare tumor with no known clinical characteristics or known epidemiological data. The tumor resembles papillary carcinomas from other organ sites, in particular ovary, tube and lung that are the main differential diagnoses. The cytological features have not been described.
Figure 8: Invasive, micropapillary carcinoma.

a. Magnification x 400, HE. Micropapillary carcinoma groups with high grade nuclear atypia (G3)

b. Magnification x 100, MGG. Numerous micropapillary epithelial cell groups
